Prospects for an Engineering Discipline of Software

The term "software engineering" was coined in 1968 as a statement of aspiration—a sort of rallying cry. That year, the North Atlantic Treaty Organization convened a workshop by that name to assess the state and prospects of software production. Capturing the imagination of software developers, the NATO phrase "software engineering" achieved popularity during the 1970s. It now refers to a collection of management processes, software tooling, and design activities for software development. The resulting practice, however, differs significantly from the practice of older forms of engineering.

What is engineering?
"Software engineering" is a label applied to a set of current practices for development. But using the word "engineering" to describe this activity takes considerable liberty with the common use of that term. The more customary usage refers to the disciplined application of scientific knowledge to resolve conflicting constraints and requirements for problems of immediate, practical significance.

Definitions of "engineering" abound. Although details differ, they share some common clauses:

* Creating cost-effective solutions ... 

... is not just about solving problems; it is about solving problems with economical use of all resources, including money.

* ... to practical problems ... 

Engineering deals with practical problems whose solutions matter to people outside the engineering domain—the customers.

* ... by applying scientific knowledge ... 

Engineering solves problems in a particular way: by applying science, mathematics, and design analysis.

* ... to building things ... 

Engineering emphasizes the solutions, which are usually tangible artifacts.

* ... in the service of mankind. 

Engineering not only serves the immediate

Software engineering
is not yet a true engineering discipline, but it has the potential to become one. Older engineering fields suggest the character software engineering might have.

November 1990
customer, but it also develops technology and expertise that will support the society. Engineering relies on codifying scientific knowledge about a technological problem domain in a form that is directly useful to the practitioner, thereby providing answers for questions that commonly occur in practice. Engineers of ordinary talent can then apply this knowledge to solve problems far faster than they otherwise could. In this way, engineering shares prior solutions rather than relying always on virtuoso problem solving.

Engineering practice enables ordinary practitioners so they can create sophisticated systems that work — spectacularly, perhaps, but reliably. The history of development is marked by both successes and failures. The successes have often been virtuoso performances or the result of diligence and hard work. The failures have often reflected poor understanding of the problem to be solved, m inaction of solution to problem, or inadequate flow-through from design to implementation. Some failed by never working, others by overrunning cost and schedule budgets.

In current software practice, knowledge about techniques that work is not shared effectively with later projects, nor is there a large body of development knowledge organized for ready reference. Computer science has contributed some relevant theory, but practice proceeds largely independently of this knowledge. Given this track record, there are fundamental problems with the use of the term "software engineer."

Routine and innovative design. Engineering design tasks are of several kinds. One of the most significant distinctions separates routine from innovative design. Routine design involves solving familiar problems, reusing large portions of prior solutions. Innovative design, on the other hand, involves finding novel solutions to unfamiliar problems. Original designs are much more rarely needed than routine design, so the latter is the bread and butter of engineering.

Most engineering disciplines capture, organize, and share design knowledge to make routine design simpler. Handbooks and manuals are often the carriers of this organized information. But current notations for software designs are not adequate for the task of both recording and communicating designs, so they fail to provide a suitable representation for such handbooks.

Software in most application domains is treated more often as original than routine — certainly more so than would be necessary if we captured and organized what we already know. One path to increased productivity is identifying applications that could be routine and developing appropriate support.

The current focus on reuse emphasizes capturing and organizing existing knowledge of a particular kind: knowledge expressed in the form of code. Indeed, sub-routine libraries — especially of system calls and general-purpose mathematical routines — have been a staple of programming for decades. But this knowledge cannot be useful if programmers do not know about it or are not encouraged to use it. Furthermore, library components require more care in design, implementation, and documentation than similar components that are simply embedded in systems.

Practitioners recognize the need for mechanisms to share experiences with good designs. This cry from the wilderness appeared on the Software Engineering News Group, a moderated electronic mailing list:

"In Chem E, when I needed to design a heat exchanger, I used a set of references that told me what the constants were ... and the standard design equations. ...

"In general, unless I, or someone else in my [software] engineering group, has read or remembers and makes known a solution to a past problem, I'm doomed to recreate the solution. ... I guess ... the critical difference is the ability to put together little pieces of the problem that are relatively well known, without having to generate a custom solution for every application."

I want to make it clear that I am aware of algorithm and code libraries, but they are incomplete solutions to what I am describing. (There is no Perry's Handbook for Software Engineering.)

This former chemical engineer is complaining that software lacks the institutionalization of mechanisms of a mature engineering discipline for recording and disseminating demonstrably good designs and ways to choose among design alternatives. (Perry's Chemical Engineering Handbook, published by McGraw-Hill, is the standard design handbook for chemical engineering; it is about four inches thick and printed in tiny type on 8.5" × 11" tissue paper.)

Model for the evolution of an engineering discipline. Historically, engineering has emerged from ad hoc practice in two stages: First, management and production techniques enable routine production. Later, the problems of routine production stimulate the development of a supporting science; the mature science eventually merges with established practice to yield professional engineering practice. Figure 1 shows this model.

The exploitation of a technology begins with craftsmanship: A set of problems must be solved, and they get solved any which way. They are solved by talented amateurs and by virtuosos, but no distinct professional class is dedicated to problems of this kind. Intuition and brute force are the primary movers in design and construction. Progress is haphazard, particularly before the advent of good communication; thus, solutions are invented and reinvented. The transmission of knowledge between craftsmen is slow, in part because of underdeveloped communications, but also because the talented amateurs often do not recognize any special need to communicate.

Nevertheless, ad hoc practice eventually moves into the folklore. This craft stage of development sees extravagant use of available materials. Construction or manufacture is often for personal or local use or for barter, but there is little or no large-scale production in anticipation of resale. Community barn raisings are an example...
of this stage; so is software written by ap- plication experts for their own ends.

At some point, the product of the tech- nology becomes widely accepted and de- mand exceeds supply. At that point, at- tempts are made to define the resources necessary for systematic commercial man- ufacture and to marshal the expertise for exploiting these resources. Capital is needed in advance to buy raw materials, so financial skills become important, and the operating scale increases over time.

As commercial practice flourishes, skilled practitioners are required for cul- tivation and for consistency of effort. They are trained pragmatically in established procedures. Management may not know why these procedures work, but they know the procedures do work and how to teach

The procedures are refined, but the re- finement is driven pragmatically. A mod- ification is tried to see if it works, then incorporated in standard procedure if it does. Economic considerations lead to concerns over the efficiency of proce- dures and the use of materials. People begin to explore ways for production facil- ities to exploit the technology base; eco- nomic issues often point out problems in commercial practice. Management strate- gies for controlling development fit at this point of the model.

The problems of current practice often stimulate the development of a corre- sponding science. There is frequently a strong, productive interaction between commercial practice and the emerging science. At some point, the science becomes sufficiently mature to be a signifi- cant contributor to the commercial prac- tice. This marks the emergence of engi- neering practice in the sense that we know it today—sufficient scientific basis to en- able a core of educated professionals so they can apply the theory to analysis of problems and synthesis of solutions.

For most disciplines, this emergence oc- curred in the 18th and early 19th centu- ries as the common interests in basic phys- ical understandings of natural science and engineering gradually drew together. The reduction of many empirical engi- neering techniques to a more scientific basis was essential to further engineering progress. And this laid the foundation fur- ther advances in natural science. "An im- portant and mutually stimulating tie-up between natural and engineering science, a development [that] had been discour- aged for centuries by the long-dominant influence of early Greek thought, was at long last consummated," wrote historian James R. Finch.1

The emergence of an engineering discipline less technological development pass limits previously imposed by relying on in- tuition; progress frequently becomes de- pendent on science as a forcing function. A scientific basis is needed to drive analy- ses, which enables new applications and even market segmentation via product va- riety. Attempts are made to gain enough control over design to target specific produc- tics on demand.

Thus, engineering emerges from the commercial exploitation that supplants craft. Modern engineering relies critically on adding scientific foundations to craft and commercialization. Exploiting tech- nology depends not only on scientific en- gineering but also on management and the marshaling of resources. Engineering and science support each other: Engineer- ing generates good problems for science, and science, after finding good problems in the needs of practice, returns workable solutions. Science is often not driven by the immediate needs of engineering; how- ever, good scientific problems often fol- low from an understanding of the prob- lems that the engineering side of the field is coping with.

The engineering practice of software has recently come under criticism for lacking a scientific basis. The usual curr- iculum has been attacked for neglecting mathematics2 and engineering science.3 Although current software practice does not match the usual expectations of an en- gineering discipline, the model described here suggests that vigorous pursuit of ap- plicable science and the reduction of that science to practice can lead to a sound en- gineering discipline of software.

Examples from traditional engineering. Two examples make this model concrete: the evolution of engineering disciplines as demonstrated by civil and chemical en- gineering. The comparison of the two is also illuminating, because they have very different basic organizations.

Civil engineering: a basis in theory. Origi- nally so-called to distinguish it from mili- tary engineering, civil engineering in- cluded all of civilian engineering until the middle of the 19th century. A divergence of interest led engineers specializing in other technologies to break away, and today civil engineers are the technical ex- perts of the construction industry. They are concerned primarily with large-scale, capital-intensive construction efforts, like build- ings, bridges, dams, tunnels, canals, highways, railroads, public water supplies, and sanitation. As a rule, civil-engineering efforts involve well-defined task groups that use appropriate tools and technolo-
The mid-18th century also saw the first attempts to apply exact science to practical building. Pope Benedict ordered an analysis of St. Peter's dome in 1742 and 1743 to determine the cause of cracks and propose repairs; the analysis was based on the principle of virtual displacement and was carried out precisely (although the model is now known to fail to account properly for elasticity). By 1850, it was possible for Robert Stephenson's Britannia Tubular Bridge over the Menai Strait between Wales and England to be subjected to a formal structural analysis. Thus, even after the basic theories were in hand, it took another 150 years before the theory was rich enough and mature enough to have direct utility at the scale of a bridge design.

Civil engineering is thus rooted in two scientific theories, corresponding to two classical problems. One problem is the composition of forces: finding the resultant force when multiple forces are combined. The other is the problem of bending: determining the forces within a beam supported at one end and weighted at the other. Two theories, statics and strength of materials, solve these problems; both were developed around 1700. Modern civil engineering is the application of these theories to the problem of constructing buildings.

For nearly two centuries, civil engineering has undergone an irresistible transition from a traditional craft, concerned with tangible fashioning, towards an abstract science, based on mathematical calculation. Every new result of research in structural analysis and technology of materials signified a more rational design, more economic dimensions, or entirely new structural possibilities. There were no apparent limitations to the possibilities of analytical approach; there were no apparent problems in building construction (that) could not be solved by calculation;" wrote the Hans Straub in his history of civil engineering. You can date the transition from craft to commercial practice to the Romans' extensive transportation system of the first century. The underlying science emerged about 1700, and it matured to successful application in practice sometime in the mid-18th century and the mid-19th century. Figure 2 places civil engineering's significant events on my model of engineering evolution.

Chemical engineering: a basis in practice. Chemical engineering is a very different kind of engineering than civil engineering. This discipline is rooted in empirical observations rather than in a scientific theory. It is concerned with practical problems of chemical manufacture; its scope covers the industrial-scale production of chemical goods: solvents, pharmaceuticals, synthetic fibers, rubber, paper, dyes, fertilizers, petroleum products, cooking oils, and so on. Although chemistry provides the specification and design of the basic sections, the chemical engineer is responsible for scaling the reactions up from laboratory scale to factory scale. As a result, chemical engineering depends as heavily on mechanical engineering as on chemistry.

Until the late 18th century, chemical production was largely a cottage industry. The first chemical produced at industrial scale was alkali, which was required for the manufacture of glass, soap, and textiles. The first economical industrial process for alkali emerged in 1789, well before the atomic theory of chemistry explained the underlying chemistry. By the mid-19th century, industrial production of dozens of chemicals had turned the British Midlands into a chemical-manufacturing district. Laws were passed to control the resulting pollution, and pollution-control inspectors, called alkali inspectors, monitored plant compliance. One of these alkali inspectors, G.E. Davis, worked in the Manchester area in the late 1840s. He realized that, although the plans he was inspecting manufactured dozens of different kinds of chemicals, there were not dozens of different
procedures involved. He identified a collection of functional operations that took place in those processing plants and were used in the manufacture of different chemicals. He gave a series of lectures in 1887 at the Manchester Technical School.

The ideas in those lectures were imported to the US by the Massachusetts Institute of Technology in its early years and form the basis of chemical engineering as it is practiced today. This structure is called unit operations: the term was coined in 1915 by Arthur D. Little.

The fundamental problems of chemical engineering are the quantitative control of large masses of material in reaction and the design of cost-effective industrial-scale processes for chemical reactions.

The unit-operations model asserts that industrial chemical-manufacturing processes can be resolved into a relatively few units, each of which has a definite function and each of which is used repeatedly in different kinds of processes. The unit operations are steps like filtration and clarification, heat exchange, distillation, screening, magnetic separation, and flotation. The basis of chemical engineering is thus a pragmatically determined collection of very high-level functions that adequately and appropriately describe the processes to be carried out.

"Chemical engineering as a science ... is not a composite of chemistry and mechanical and civil engineering, but a science in itself, the basis of which is that in their proper sequence and coordination constitute a chemical process as conducted on the industrial scale. These operations ... are not the subject matter of chemistry as such nor of mechanical engineering. Their treatment is in the quantitative way, with proper exposition of the laws controlling them and of the materials and equipment concerned in them," the American Institute of Chemical Engineers Committee on Education wrote in 1922.

This is a very different kind of structure from that of civil engineering. It is a pragmatic, empirical structure—not a theoretical one.

You can date the transition from craft to commercial practice to the introduction of the LeBlanc process for alkali in 1789. The science emerged with the British chemist John Dalton's atomic theory in the early 19th century, and it matured to successful merger with large-scale mechanical processes in the 1890s. Figure 3 places chemical engineering's significant events on my model.

**Software technology**

Where does software stand as an engineering discipline? For software, the problem is appropriately an engineering problem: creating cost-effective solutions to practical problems, building things in the service of mankind.

**Information processing as an economic force.** The US computer business— including computers, peripherals, packaged software, and communications— was about $150 billion in 1989 and is projected to be more than $230 billion by 1992. The packaged-software component is projected to grow from $23.7 billion to $37.5 billion in this period, according to the Data Analysis Group's fourth-quarter 1989 forecasts. Services, including systems integration and in-house development, are not included in these figures.

Worldwide, software sales amounted to about $65 billion in 1989. This does not include the value of in-house development, which is a much larger activity. World figures are hard to estimate, but the cost of in-house software in the US alone may be in the range of $150 billion to $200 billion. It is not clear how much modification after release (so-called "maintenance") is included in this figure. Thus, software is coming to dominate the cost of information processing.

The economic presence of information processing also makes itself known through the actual and opportunity costs of systems that do not work. Examples of costly system failures abound. Less obvious are the costs of computing that is not even tried: development backlogs so large that they discourage new requests, gigabytes of unprocessed raw data from satellites and space probes, and so on. Despite very real (and substantial) successes, the litany of mismatches of cost, schedule, and expectations is a familiar one.

Growing role of software in critical applications. The US National Academy of Engineering recently selected the 10 greatest engineering achievements of the last 25 years. Of the three, are informatics achievements: communications and information-gathering satellites, the microprocessor, and fiber-optic communications. Two more are direct applications of computers: computer-aided design and manufacturing and the computerized axial tomography scan. And most of the rest are computer-intensive: the Moon landing, advanced composite materials, the jumbo jet, lasers, and the application of genetic engineering to produce new pharmaceuticals and crops.

The conduct of science is increasingly driven by computational paradigms standing on equal footing with theoretical and experimental paradigms. Both scientific and engineering disciplines require very sophisticated computing. The demands are often stated in terms of raw processing power—"an exaflop (10^18) processor with teraword memory," a petabyte (10^15) of storage," as one article put it— but the supercomputing community is increasingly recognizing development, not mere raw processing, as a critical bottleneck.

Because of software's pervasive presence, the appropriate objective for its developers should be the effective delivery of computational capability to real users in forms that match their needs. The dis-

Distinction between a system's computational component and the application it serves is often very soft — the development of effective software now often requires substantial application expertise.

**Maturity of development techniques.** Our development abilities have certainly improved over the 40 or so years of programming experience. Progress has been both qualitative and quantitative. Moreover, it has taken different forms in the worlds of research and practice.

One of the most familiar characteristics of this progress has been the shift from programming-in-the-small to programming-in-the-large. It is also useful to look at a shift that took place 10 years before that, from programming any-way to programming-in-the-small. Table 1 summarizes these shifts, both of which describe the focus of attention of the software research community.

Before the mid-1960s, programming was substantially ad hoc; it was a significant accomplishment to get a program to run at all. Complex software systems were created — some performed very well — but their construction was either highly empirical or a virtuoso activity. To make programs intelligible, we used mnemonics, we tried to be precise about writing comments, and we wrote prose specifications. Our emphasis was on small programs, which was all we could handle predictably.

We did come to understand that computers are symbolic information processors, not just number crunchers — a significant insight. But the abstractions of algorithms and data structures did not emerge until 1967, when Donald Knuth showed the utility of thinking about them in isolation from the particular programs that happened to implement them.

A similar shift in attitudes about specifications took place at about the same time, when Robert Floyd showed how attaching logical formulas to programs allows formal reasoning about the programs. Thus, the late 1960s saw a shift from crafting monolithic programs to an emphasis on algorithms and data structures. But the programs in question were still simple programs that execute once and then terminate.

You can view the shift that took place in the mid-1970s from programming-in-the-small to programming-in-the-large much the same terms. Research attention turned to complex systems whose specifications were concerned not only with the functional relations of the inputs and outputs, but also with performance, reliability, and the states through which the system passed. This led to a shift in emphasis to interfaces and managing the programming process.

In addition, the data of complex systems often outlives the programs and may be more valuable, so we learned that we now have to worry about integrity and consistency of databases. Many of our programs (for example, the telephone switching system or a computer operating system) should not terminate; these systems require a different sort of reasoning than do programs that take input, compute, produce output, and terminate. In systems that run indefinitely, the sequence of system states is often much more important than the (possibly undesirable) termination condition.

The tools and techniques that accompanied the shift from programming-any-way to programming-in-the-small provided first steps toward systematic, routine development of small programs; they also seeded the development of a science that has matured only in the last decade. The tools and techniques that accompanied the shift from programming-in-the-small to programming-in-the-large were largely geared to supporting groups of programmers working together in orderly ways and in giving management a view into production processes. This directly supports the commercial practice of development.

Practical development proceeded to large complex systems much faster than the research community did. For example, the Sage missile-defense system of the 1950s and the Sabre airline-reservation system of the 1960s were successful interactive systems on a scale that far exceeded the maturity of the science. They appear to have been developed by excellent engineers who understood the requirements well and applied design and development methods from other (like electrical) engineering disciplines. Modern development methodologies are management procedures intended to guide large numbers of developers through similar disciplines.

The term "software engineering" was introduced in 1968 to name a conference...
convened by NATO to discuss problems of software production. Despite the label, most of the discussion dealt with the challenge of progressing from the craft stage to the commercial stage of practice. In 1976, Barry Boehm proposed the definition of the term as "the practical application of scientific knowledge in the design and construction of computer programs and the associated documentation required to develop, operate, and maintain them." This definition is consistent with traditional definitions of engineering, although Boehm noted the shortage of scientific knowledge to apply.

Unfortunately, the term is now most often used to refer to life-cycle models, routine methodologies, cost-estimation techniques, documentation frameworks, configuration-management tools, quality-assurance techniques, and other techniques for standardizing production activities. These technologies are characteristic of the commercial stage of evolution — "software management" would be a much more appropriate term.

Scientific basis for engineering practice. Engineering practice emerges from commercial practice by exploiting the results of a companion science. The scientific results must be mature and rich enough to model practical problems. They must also be organized in a form that is useful to practitioners. Computer science has a few models and theories that are ready to support practice, but the packaging of these results for operational use is lacking.

Maturity of supporting science. Despite the criticism sometimes made by software producers that computer science is irrelevant to practical software, good models and theories have been developed in areas that have had enough time for the theories to mature.

In the early 1960s, algorithms and data structures were simply created as part of each program. Some folklore grew up about good ways to do certain sorts of things, and it was transmitted informally. By the mid-1960s, good programmers shared the intuition that if you get the data structures right, the rest of the program is much simpler. In the late 1960s, algorithms and data structures began to be abstracted from individual programs, and their essential properties were described and analyzed.

The 1970s saw substantial progress in supporting theories, including performance analysis and correctness. Concurrently, the programming implications of these abstractions were explored; abstract-data-type research dealt with such issues as:

- Specifications: abstract models and algebraic axioms.
- Software structure: bundling representation with algorithms.
- Language issues: modules, scope, and user-defined types.
- Information hiding: protecting the integrity of information not in the specification.
- Compositionality: invariants of data structures.
- Composition rules: declarations.

Both sound theory and language support were available by the early 1980s, and routine good practice now depends on this support.

Compiler construction is another good example. In 1960, simply writing a compiler at all was a major achievement; it is not clear that we really understood what a higher level language was. Formal syntax was first used systematically for Algol 60, and tools for processing it automatically (then called compiler compilers, but now called parser generators) were first developed in the 1960s and made practical in the 1970s. Also in the 1970s, we started developing theories of semantics and types, and the 1980s have brought significant progress toward the automation of compiler construction.

Both of these examples have roots in the problems of the 1960s and became genuinely practical in the 1980s. It takes a good 20 years from the time that work starts on a theory until it provides serious assistance to routine practice. Development periods of comparable length have also preceded the widespread use of systematic methods and technologies like structured programming, Smalltalk, and Unix, as Sam Redwine and colleagues have shown.

But the whole field of computing is only about 40 years old, and many theories are emerging in the research pipeline.

Interaction between science and engineering. The development of good models within the software domain follows this pattern:

- Engineers begin by solving problems anyway we can. After some time, we distinguish in those ad hoc solutions things that usually work and things that do not usually work. The ones that do work enter the folklore. People tell each other about them informally. As the folklore becomes more and more systematic, we codify it as written heuristics and rules of procedure.
- Eventually, that codification becomes crisp enough to support models and theories, together with the associated mathematics. These can then help improve practice.

November 1990
and experience from that practice can sharpen the theories. Furthermore, the improvement in practice let us think about harder problems — which we first solve ad hoc, then find heuristics for, eventually develop new models and theories for, and so on. Figure 4 illustrates this cycle. The models and theories do not have to be fully fleshed out for this process to assist practice: The initial codification of folklore may be useful in and of itself. This progression is illustrated in the use of machine language for control flow in the 1960s. In the late 1950s and the early 1960s, we did not have crisp notions about what an iteration or a conditional was, so we laid down special-purpose code, building each structure individually out of tests and branch instructions. Eventually, a small set of patterns emerged as generally useful, generally easy to get right, and generally at least as good as the alternatives. Designers of higher level languages explicitly identified the most useful ones and codified them by producing special-purpose syntax. A formal result about the completeness of the structured constructs provided additional reassurance. Now, almost nobody believes that new kinds of loops should be invented as a routine practice. A few kinds of iterations and a few kinds of conditions are captured in the languages. They are taught as control concepts that go with the language; people use them routinely, without concern for the underlying machine code. Further experience led to verifiable formal specifications of these statements' semantics and of the programs that used them. Experience with the formalization in turn refined the statements supported in the programming languages. In this way, ad hoc practice entered a period of folklore and eventually matured to have conventional syntax and semantic theories that explain it.

Where is software? Where, then, does current software practice lie on the path to engineering? It is still in some cases craft and in some cases commercial practice. A science is beginning to contribute results, and, for isolated examples, you can argue that professional engineering is taking place. (Figure 5 shows where software practice fits on my model.) That is not, however, the common case. There are good grounds to expect that there will eventually be an engineering discipline of software. Its nature will be technical, and it will be based in computer science. Although we have not yet mastered that state, it is an achievable goal. The next tests for the software profession are:

1. To pick an appropriate mix of short-term, pragmatic, possible purely empirical contributions that help stabilize commercial practice and
2. To invest in long-term efforts to develop and make available basic scientific contributions.

The profession must take five basic steps on its path to becoming a true engineering discipline:

1. Understand the nature of expertise. Proficiency in any field requires not only higher order reasoning skills but also a large store of facts together with a certain amount of context about their implications and appropriate use. Studies have demonstrated this across a wide range of problem domains, including medical diagnosis, physics, chess, financial analysis, architecture, scientific research, policy decision making, and others. As Herbert Simon described in the paper "Human Experts and Knowledge-Based Systems" presented at the 1987 IFIP Working Conference on Concepts and Characteristics of Knowledge-Based Systems.

2. Thunk fluency in a domain requires content and context as well as skill. In the case of natural-language fluency, E.D. Hirsch has argued that abstract skills have driven out context; students are expected (unrealistically) to learn general skills from a few typical examples rather than by a "piling up of information"; and intellectual and social skills are supposed to be developed naturally without regard to the specific content.

However, Hirsch wrote, specific information is important at all stages. Not only are the specific facts important in their own right, but they serve as carriers of shared culture and shared values. A software engineer's expertise includes facts about computer science in general, software design elements, programming idioms, representations, and specific knowledge about the program of current interest. In addition, it requires skill with tools: the language, environment, and support software with which this program is implemented.

Hirsch provided a list of some 5,000 words and concepts that represent the information actually possessed by literate Americans. The list goes beyond simple vocabulary to enumerate objects, concepts, idioms, and phrases that implicitly invoke cultural content beyond their dictionary definitions. Whether or not you agree in detail with its composition, the list and accompanying argument demonstrate the need for communication as well as denotations of the vocabulary.

Similarly, a programmer needs to know not only a programming language but also the tools and theories that underlie it. The list and accompanying argument demonstrate the need for communication as well as denotations of the vocabulary.
be familiar with the global definitions of the program of current interest and the rules about their use. In addition, a developer of application software must understand application-area issues.

Simply put, the engineering of software would be better supported if we knew better what specific content a software engineer should know. We could organize the teaching of this material so useful subcases are learned first, followed by progressively more sophisticated subcases. We could also develop standard reference materials as carriers of the content.

Recognize different ways to get information. Given that a large body of knowledge is important to a working professional, we as a discipline must ask how software engineers should acquire the knowledge, either as students or as working professionals. Generally speaking, there are three ways to get a piece of information you need: You can remember it, you can look it up, or you can derive it. These have different distributions of costs, as Table 2 shows.

Incorporation requires a relatively large initial investment in learning the material, which is then available for instant use. Reference materials require a large investment by the profession for developing both the organization and the content; each student must then learn how to use the reference materials and then do so as a working professional.

Deriving information may involve ad hoc creation from scratch, it may involve instantiation of a formal model, or it may involve inferring meaning from other available information. To the extent that formal models are available, their formulation requires a substantial initial investment. Students first learn the models, then apply them in practice. Because each new application requires the model to be applied anew, the cost in use may be very high.

Each professional's allocation of effort among these alternatives is driven by what he has already learned, by habits developed during that education, and by the reference materials available. Today, general-purpose reference material for software is scarce, although documentation for specific computer systems, languages, and applications may be extensive. Even when documentation is available, however, it may be underserved because it is poorly indexed or because developers have learned to prefer fresh derivation to use of existing solutions. The same is true of subroutine libraries.

Simply put, software engineering requires investment in the infrastructure cost in creating the materials required to organize information, especially reference material for practitioners.

Encourage routine practice. Good engineering practice for routine design depends on the engineer's command of factual knowledge and design skills and on the quality of reference materials available. It also depends on the incentives and values associated with innovation.

Unfortunately, computer-science education has prepared developers with a background that emphasizes fresh creation almost exclusively. Students learn to work alone and to develop programs from scratch. They are rarely asked to understand software systems they have not written. However, just as natural-language fluency requires instant recognition of a core vocabulary, programming fluency should require an extensive vocabulary of definitions that the programmer can use familiarly, without repeated recourse to documentation.

Fred Brooks has argued that one of the great hopes for software engineering is the cultivation of great designers. Indeed, innovative designs require great designers. But great designers are rare, and most designs need not be innovative. Systematic presentation of design fragments and techniques that are known to work can enable designers of ordinary talent to produce effective results for a wide range of more routine problems by using prior results (buying or growing, in Brookes's terms) instead of always building from scratch.

It is unreasonable to expect a designer or developer to take advantage of scientific theories or experience if the necessary information is not readily available. Scientific results need to be recast in operational form; the important information from experience must be extracted from examples. The content should include design elements, components, interfaces, interchange representations, and algorithms. A conceptual structure must be developed so the information can be found when it is needed. These facts must be augmented with analysis techniques or guidelines to support selection of alternatives that best match the problem at hand.

A few examples of well-organized reference materials already exist. For example, the questionnaire flowchart of William Martin's sorting survey captured in one page the information a designer needed to choose among the then current sorting techniques. William Cody and William Wait's manual for implementing elementary mathematical functions gives each function the basic strategy and special considerations needed to adapt that strategy to various hardware architectures. Although engineering has traditionally relied on handbooks published in book form, a software engineers' handbook must be on line and interactive. No other alternative allows for rapid distribution of information at the rate this field changes, and no other alternative has the potential for smooth integration with on-line design tools. The on-line incorporation will require solutions to a variety of electronic-publishing problems, including distribution, validation, organization and search, and collection and distribution of royalties.

Simply put, software engineering would benefit from a shift of emphasis in which both reference materials and case studies of exemplary software designs are incorporated in the curriculum. The discipline must find ways to reward preparation of material for reference use and the development of good case studies.

Expect professional specializations. As software practice matures toward engineering, the body of substantive technical knowledge required of a designer or developer continues to grow. In some areas, it has long since grown large enough to
require specialization — for example, database administration was long ago sepa-
arázed from the corresponding program-
ing. But systems programming has been
resistant to explicit recognition of profes-
sional specialties.
In the coming decade, we can expect to
see specialization of two kinds:
• internal specialization as the technical
contain in the core of software grows
deeper and
• external specialization with an in-
creased range of applications that require
both substantive application knowledge
and substantive computing knowledge.

In general, specialties are already start-
ing to be recognizable for communications,
reliability, real-time programming, scien-
tific computing, and graphics, among oth-
er. Because these specialties rely critically
on mastery of a substantial body of com-
puter science, they may be more appropri-
ately organized as postbaccalaureate edu-

cation.

External specialization is becoming
common, but the required dual expertise
is usually acquired informally (and often
incompletely). Computational specialization
in various disciplines can be sup-
ported via joint programs involving both
computer science and the application de-
partment; this is being done at some uni-
versities.

Simply put, software engineering will re-
quire explicit recognition of specialties.
Educational opportunities should be pro-
vided to support them. However, this
should not be done at the cost of a solid
foundation in computer science and, in
the case of external specialization, in the
application discipline.

Improve the coupling between science
and commercial practice. Good science is
often based on problems underlying the
problems of production. This should be
as true for computer science as for any
other discipline. Good science depends
on strong interactions between research-
ers and practitioners. However, cultural
differences, lack of access to large, com-
plex systems, and the sheer difficulty of
understanding those systems have inter-
fered with the communication that sup-
ports these interactions.

Similarly, the adoption of results from the
research community has been im-
peded by poor understanding of how to
turn a research result into a useful ele-
ment of a production environment. Some
companies and universities are already
developing cooperative programs to
bridge this gap, but the logistics are often
daunting.

Simply put, an engineering basis for
software will evolve faster if constructive
interaction between research and produc-
tion communities can be nurtured.

Acknowledgments
This article benefited from comments by
Allen Newell, Norus Gilits, Frank Friedman,
Tom Lane, and the other authors of articles in
this special issue. Most importantly, Elidon Shaw
fostered my appreciation for engineering.
Without his support, this work would not have been
possible, so I dedicate this article to his memory.

This work was supported by the US Defense
Dept. and a grant from Moby Corp.

Mary Shaw is a professor of computer science at
Carnegie Mellon University where she has been
on the faculty since 1971. From 1984 to 1987, she was
chief scientist at the Software Engineering Institute,
with which she still has a joint appointment. Her primary research
interests are programming systems and software
engineering, particularly abstraction tech-
niques and language tools for developing and
evaluating software.

Shaw received a B.A. in mathematics from
Rice University and a Ph.D. in computer science
from Carnegie Mellon University. She is a member of the IEEE Computer Society, ACM,
New York Academy of Sciences, and Sigma Xi.
She also serves on the National Research Council’s Computer Science and Technology
Board, IEEE Technical Committee on Soft-
ware Engineering, and HIP Working Group 2.4 (System Implementation Languages).

Addressee questions about this article to the
author at Computer Science Dept., Carnegie
Mellon University, Pittsburgh, PA 15213-3890.

Mary Shaw served as the editor of The

IEEE Software
